Case Report

Hypoglycemia as first presentation of insulin resistance–A case report

Sourya Sourabh Mohakuda¹ and J Muthukrishnan^{2*}

¹Clinical Tutor, General Medicine, AFMC, Pune, India

Abstract

Post prandial hypoglycemia refers to low blood glucose levels in the post meal period. In absence of any gastro-intestinal abnormality or surgery, other less common conditions need consideration. Extended glucose tolerance test helps confirm the diagnosis. The timing of hypoglycemia post meals and the corresponding insulin and C-peptide values help in understanding its pathophysiology. Hyperinsulinemia in Insulin resistance can also rarely present initially with post meal hypoglycemia. Frequent low glycemic index meals along with alpha-glucosidase inhibitors help alleviating the symptoms. We report this case for its rarity and clinical relevance.

Introduction

There is no clear cut consensus in defining glucose levels that defines hypoglycaemia. However in practice, plasma glucose level (BG) below 54mg/dl in non-diabetic individuals and below 70mg/dl in diabetics is considered as hypoglycaemia [1].

In non-diabetic individuals the hypoglycaemia can be either fasting or post prandial. While insulinoma is suspected in cases with fasting hypoglycaemia, dumping syndromes predominate the causes for post prandial hypoglycaemia [2,3].

We present a case with late onset post prandial hypoglycaemic symptoms and discuss the approach and management of such a problem.

Case presentation

A 55-year old lady, presented to the out-patient department with complaints of several episodes of dizziness 3-4hours post meals for a period of one year. She had no other significant past illness or surgeries and was not on any drugs. She was obese (Wt 77.8kg, BMI 32kg/m², waist circumference 104cm). Her pulse was 76per min, blood pressure was 126/80mmHg. She had markers of insulin resistance in the form of acanthosis nigricans and skin tags. Systemic examination was normal.

Her fasting plasma glucose was 98mg/dl, HDL 34mg/dl and triglycerides level was 168mg/dl. She used to keep fasts for 24hours off and on for religious purpose and had no history suggestive of similar episodes in those days.

A possibility of post prandial hypoglycaemia was considered and she was advised to check her blood glucose levels with a glucometer when symptomatic. The relevant findings during these episodes are as given below Table 1.

Based on the above findings, she was subjected to a extended Glucose Tolerance Test (eGTT) in which 75gm of glucose post 10 hours of fasting was administered orally and the blood samples were drawn every 60mins for next 4hours. Care was taken to stop the test if symptomatic hypoglycaemia develops.

Table 1: Details of events where patient was symptomatic.

| Sr No of episodes | Time elapsed post meal | Glucometer reading | Relief by biscuits/ chocolates | Time taken to get relived of symptoms |
|-------------------|------------------------|--------------------|--------------------------------|---------------------------------------|
| 1 | 2h 45mins | 54mg/dl | yes | 10-15mins |
| 2 | 2h 40mins | 46mg/dl | yes | 10-15mins |
| 3 | 3h 10mins | 56mg/dl | yes | 10-15mins |
| 4 | 3h 05mins | 52mg/dl | yes | 10-15mins |

Her blood glucose levels were analysed from the samples Figure 1.

Although the fasting blood sugar was normal and had a physiological rise till post 2 hours. However the BSL was 62mg/dl at 3hr and 54mg/dl at 4hr of eGTT.

On the sample collected at 4th hour of eGTT and the fasting sample, serum insulin and c-peptides levels were analysed Table 2.

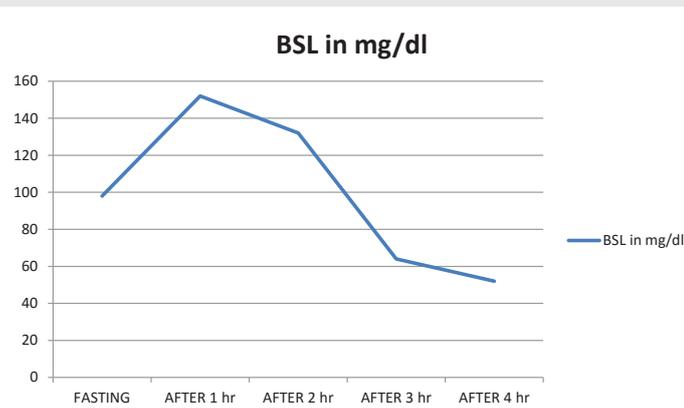

Figure 1: Profile of eGtt.

Table 2: Insulin and c peptide levels at fasting and at 4th hour of eGTT.

| | At fasting | 4hr of eGTT |
|---------------------------------------|------------|-------------|
| Insulin (μU/ml) | 14 | 22 |
| C-Peptide (nmol/l) (0.5-2.0nmol/l) | 0.72 | 0.92 |

The levels of insulin and c peptide were disproportionately high in the setting of hypoglycaemia where it was expected to be nearly absent.

Her homeostatic model assessment score for insulin resistance (HOMA-IR) based on fasting glucose and insulin levels were 3.39, suggestive of moderate insulin resistance.

Her renal and liver functions were normal. Radiological imaging of the abdomen did not reveal any abnormality. An upper gastrointestinal endoscopy was done which revealed a normal study. She was explained to be on frequent low caloric meal which contained food with low glycemic index such as green vegetable and fruit. High glycemic index contents such as bakery, refined flour, rice and potatoes were avoided. Regular exercise was emphasised to target a weight loss of 3-4kg in 3months. She was also started on Tab Acarbose 25mg thrice a day with the major meals. She has been of follow up since last 01year, achieved weight loss of 5kgs and has been asymptomatic. An extended GTT was repeated after 01month which revealed a normal study. In view of hyperinsulinemic hypoglycaemia, with an elevated HOMA-IR, and no other etiology found to explain post-prandial hypoglycaemia, she was diagnosed to have insulin resistance leading to post

prandial hypoglycaemia. She has been advised regular follow up for recurrence of symptoms and development of DM.

Discussion

Post prandial hypoglycaemia which occurs around 2-4 hours post meal is suggestive of a late dumping syndrome. The influx of carbohydrate into the intestine causing inappropriately high insulin secretion is one explanation of this phenomenon. The above explanation holds good when there is a prior surgery involving the gastrointestinal tract causing anatomical and physiological deregulation in intestinal motility.

In an individual with no such abnormality, with clinical features and HOMA-IR score suggestive of insulin resistance, it is the likely cause for post prandial hypoglycaemia. In obese individuals and in patients with metabolic syndrome, such events have been described. There are four Glucose transporters (GLUT) in the body, numbered GLUT1-4 [2]. Amongst these, the GLUT 1-3 is independent of insulin for their functioning while GLUT 4 is insulin dependent. In individuals with metabolic syndrome, underlying insulin resistance is the primary defect. Post meals, the GLUT 1-3 receptors activate and cause the post prandial surge of glucose to normalise. Although the insulin secretion keeps increasing at this stage, the insertion of GLUT-4 receptor is delayed in the background of insulin resistance. When the blood glucose level is normalised, the absolute increase in insulin levels cause the small amount of GLUT4 receptors to insert at the target. This small amount of GLUT4 receptors can cause hypoglycaemia when the blood glucose level is normal. This pathophysiology also explains why rarely Type 2 diabetics present as post prandial hypoglycaemia as their first symptom in the initial course of their disease.

Our case had clinical features and biochemical evidence (HOMA-IR) to suggest insulin resistance. The timing of hypoglycaemia post meals, disproportionately raised insulin and C-peptide levels at hypoglycaemia indicate that insulin resistance was the likely cause for her post prandial hypoglycaemia after the secondary causes were ruled out after extensive evaluation. Post prandial hypoglycaemia has been described earlier in non diabetic patients with good insulin sensitivity [3]. In our review of literature, we were not able to find any other case report of hypoglycaemia being the first presentation of insulin resistance.

Acarbose inhibits the action of glycoside hydrolases leading to slowing down of digestion of complex carbohydrates [4]. The low glycemic index food also prevent the sudden surge of plasma glucose levels which inturn neutralise the abrupt rise in the secretion of insulin [5]. Our case has remained asymptomatic with weight loss, low glycemic index food taken at regular frequent intervals and tablet Acarbose 25mg taken thrice a day. On follow up over the past one year, our case has remained asymptomatic, normoglycemic with a normal extended glucose tolerance test.
